ABSTRACT

This paper describes the processes used at the Fukushima Daiichi plant, Japan, to purify the waste effluents generated in the cooling of damaged reactors. These include primary cesium removal with the Kurion zeolite system and the SARRY system utilizing silicotitanate to remove radiocesium from water recirculated to reactors for cooling. Another process is the ALPS system to purify the retentates of the reverse osmosis plant to further purify the water from radionuclides after primary cesium separation. In ALPS, a major role is played by the transition metal hexacyanoferrate product CsTreat and sodium titanate SrTreat in the removal of radiocesium and radiostrontium, respectively. The performance of these four exchangers (zeolite, silicotitanate, hexacyanoferrate, and sodium titanate) are critically analysed with respect to processing capacities and the decontamination factor obtained in the processes. Furthermore, general information on preparation, structure, and ion exchange of these ion-exchanger categories are given with additional information on their use in nuclear waste effluent treatment processes. Finally, the importance of selectivity and associated factors are discussed.

INTRODUCTION

Following a major earthquake, a powerful tsunami disabled the power supply to three reactors at the Fukushima Daiichi nuclear power plant in Japan on March 11, 2011. As the fuel was not cooled these reactors melted in the following three days. Even though the nuclear chain reaction had stopped, due to the continuing radioactive decay of fission products the fuel was very hot (well above 1000^{o}C) and caused the meltdown. To cool the damaged reactors, injection of sea water with fire department trucks was initiated one to three days after onset of the accident. After approximately two weeks, electrical power was restored to the plant and fresh water was injected into the reactors instead of seawater. The injected water accumulated in the basement of the reactor buildings and in the turbine halls. The radioactivity content of the water was very high since the water was in direct contact with melted fuel. As a highly soluble and readily volatile alkali metal, radioactive cesium isotopes ^{134}Cs and ^{137}Cs formed the greatest fraction of the radioactivity in the cooling water. ^{137}Cs is a fission product with a half-life of 30 years while ^{134}Cs is a neutron activation product with a half-life of 2.1 years. They are both of great radiological concern due to emission of high-energy gamma rays. At the onset of the accident, both cesium isotopes were present at approximately the same contents in the fuel. In the seven years since the event, the fraction of ^{134}Cs activity has decreased to about 10% of that of ^{137}Cs. The second most important component in the waste waters was formed by ^{90}Sr, which has a half-life of 29 years. After the accident the waste also contained ^{89}Sr. However, due to its short half-life of just 51 days this radionuclide has decayed completely. As strontium has lower solubility and volatility than cesium, its concentration in the contaminated waters was, however, considerably lower than that of the radiocesium isotopes. In addition to radiocesium and radiostrontium, the waters contain numerous other radionuclides.

To prevent overflow of these highly contaminated waters from the reactor buildings into the sea, the operator of the plant (TEPCO, Tokyo Electric Power Company) hired contractors to build waste water treatment systems to enable circulation of the cooling water. This paper reviews the various systems constructed at the Fukushima Daiichi plant for this purpose. The performance and radionuclide separation efficiency of the systems are described. Special attention is paid to the highly selective inorganic ion exchangers CsTreat and SrTreat, which were used to separate radioactive cesium and strontium, respectively, at the far end of the separation processes. These exchangers were developed by the Radiochemistry Unit of the University of Helsinki, Finland and

the Fortum company, Finland, and are manufactured by the latter. The scientific and technical literature on Fukushima waste treatment is very limited. The data for this article were extracted mostly from TEPCO press releases (http://www.tepco.co.jp/en/press/corp-com/release/indexold-e.html). These releases contain altogether 335 reports from 2011 to 2017 entitled "Situation of storing and treatment of accumulated water including highly concentrated radioactive materials at Fukushima Daiichi Nuclear Power Station." Each report contains a schematic picture of the water treatment systems and provides water volumes and performance data. An example of such a picture is shown in Fig. 1. Later in this article, we refer to these reports as "TEPCO press releases." In addition, the TEPCO Press Conference handouts were an important source of information.

Figure 1. An example schematic of the water treatment system at the Fukushima Daiichi plant as presented in the TEPCO press releases "Situation of storing and treatment of accumulated water including highly concentrated radioactive materials at Fukushima Daiichi Nuclear Power Station" (http://www.tepco.co.jp/en/press/corp-com/release/2015/1265264_6844.html).

The Fukushima Daiichi nuclear waste effluent treatment is the largest ever nuclear waste treatment process. Various waste treatment systems and purification media, many of which represent today's best available technology, have been tested at the plant during the last eight years. Therefore, it is essential to describe and critically analyse the processes with respect to their radionuclide removal performance. This is also needed in further development of nuclear waste treatment processes and purification media.

FIRST PURIFICATION SYSTEM IN JUNE TO SEPTEMBER 2011: ZEOLITE AND COPRECIPITATION

Construction of the first system for the purification and circulation of cooling waters started in April 2011; the system was operational on June 17, 2011. This system was based on a zeolite separation of radiocesium and coprecipitation of cesium and other radionuclides. The purified water was further treated with a reverse osmosis system, from which the permeate was directed back to reactors for cooling and the saline retentate into storage tanks for further treatment (see next section). The zeolite part of the system was offered by Kurion Inc., USA, the coprecipitation by Areva/Veolia, France, and the reverse osmosis by Hitachi, Japan. In this system, zeolite separation was first, coprecipitation was second, and reverse osmosis was performed at the end.

The Kurion cesium removal system is based on four parallel lines, each with four 1.2 m^3-zeolite beds in series (Fig. 2). The zeolite used in the system is herschelite, a special-type chabazite with the general formula of $(Na_2,K_2,Ca,Sr,Mg)_2[Al_2Si_4O_{12}]_2 \times 12H_2O$. Zeolites, the tunnel-structured aluminosilicates, and their use in nuclear waste treatment are discussed in detail later.

Figure 2. The Kurion zeolite system at the Fukushima Daiichi plant for the removal of radiocesium from contaminated waters generated in the cooling of damaged reactors. In front of the zeolite beds is a surfactant-modified zeolite bed for removal of oil and technetium and at the far end a silver-impregnated zeolite bed for radioiodine removal. TEPCO Press Conference handout dated June 17, 2011.

The Areva/Veolia coprecipitation (Fig. 3) was a two-stage system consisting of Multiflo® and Actiflo® sub-systems in series (1). In this system, radiocesium is coprecipitated with nickel hexacyanoferrate (general formula $M_2NiFe(CN)_6$, where M is an alkali metal) and radiostrontium with barium sulfate ($BaSO_4$). Presumably the system also contained coprecipitation of hydrolysable metals with ferric hydroxides. At the end of the process, the sludge was separated with a lamella-settling tank. An already existing system was dismantled from a site (probably in Europe) and moved to Japan.

Figure 3. The Areva/Veolia coprecipitation system used in June to September 2011 at the Fukushima Daiichi plant to purify contaminated waters. TEPCO Press Conference handout dated October 29, 2011.

The combined Kurion-Areva/Veolia purification system was running for only three months as the Areva/Veolia part of the system was taken out of operation at the end of September 2011. During the three months, the system processed in total 80 000 m^3 of water for circulation back to the damaged reactors. In this period, the ^{137}Cs activity of the water to be treated was 1.5×10^9 Bq/L, corresponding to a chemical concentration of 3×10^{-5} mol/L. The chloride concentration, representing salinity, decreased from 16 g/L to 5 g/L. The decontamination factor (i.e., the ratio of activity concentration before treatment to that after treatment) for ^{137}Cs of the zeolite was on average fairly low (260), while the coprecipitation yielded decontamination factors between 200 and 20 000. The overall decontamination factor of the whole system was good, varying between

3×10^4 and 2×10^6. The system, however, produced large volumes of secondary waste (in total 820 m^3), of which 580 m^3 was sludge from the coprecipitation system and 240 m^3 was spent zeolite. Generation of unacceptably high volumes of secondary waste was probably the reason why the Areva/Veolia coprecipitation was completely taken out of operation. From September 2011 onwards, the Kurion zeolite system continued operation but was mostly replaced by the more efficient SARRY system utilizing silicotitanate for cesium removal.

Due to their batch operation mode nature, precipitation processes, despite using radionuclide-specific precipitation agents such as hexacyanoferrates, are far less effective than column mode processes utilizing packed beds. This is why the Areva/Veolia system had such a low processing capacity and produced such high volumes of secondary waste. Zeolites, in turn, even though they are clearly more selective than conventional organic ion-exchange resins, are not highly selective for any ions. This means that whenever the solution contains considerable concentrations of competing macro ions their separation performance for cesium is low to intermediate. The most important competing macro ions are sodium, potassium, calcium, and magnesium, which are present in all natural waters and in most nuclear waste effluents. In sea water their concentrations are 0.47 mol/L (sodium), 0.01 mol/L (potassium), 0.01 mol/L (calcium), and 0.05 mol/L (magnesium). In the early phases of purification the water was essentially sea water with a salt content of 3.5%. The first reported chloride concentration in June 2011 was 16 g/L, which is close to the average sea water concentration of 19 g/L. Tsukada et al. (2) reported that the cesium distribution coefficient of Kurion chabazite in pure water is about 15 000 ml/g while in sea water it is only about 800 ml/g (derived from data in Fig. 8 in Tsukada et al. paper) at a cesium concentration of 0.01 mmol/L. The decrease clearly illustrates the low selectivity of chabazite, true to any zeolite. Selectivity is the key factor in both the decontamination factor and processing capacity; the higher the selectivity the higher the decontamination factor and the processing capacity (discussed later in detail). At this stage we note that the distribution coefficient is directly proportional to the processing capacity. For example, if the distribution coefficient determined in batch mode is 800 ml/g, this means that 800 ml of waste can be processed to 50% breakthrough with 1 g of sorbent in a column mode. This corresponds to 0.8 m^3 per 1 kg. This is consistent with the observed performance of Kurion zeolite reported in Table 2 (0.38 m^3/kg). It is clear that in the Fukushima purification process the zeolite beds were not run to a water volume corresponding to 50% breakthrough but to a sufficiently low

volume that assured the highest achievable decontamination factor. This is why the observed processing capacity was only about half of that derived from the distribution coefficient.

From June to September 2011 reverse osmosis decreased the water salinity by a factor of 450 on average, calculated from the decrease in chloride concentration.

Table 2. Summary of the performance of the combined Areva/Veolia coprecipitation and Kurion zeolite purification system in the removal of ^{137}Cs for the water circulation in June to September 2011. Derived from data provided in TEPCO press releases.

We conclude that the first purification phase yielded high decontamination factors for radiocesium but generated unacceptably high volumes of secondary waste, precipitation sludge, and spent zeolite. The technology did not represent the best available technique but was based on established but somewhat outdated technology. It was, however, important to rapidly install a water treatment system to prevent the overflow of contaminated water from reactor buildings into the surroundings. With this respect the rapidly built zeolite/coprecipitation system worked well as a first aid.

Radionuclides of cesium

In irradiated nuclear fuel there are three radioisotopes of cesium (^{134}Cs, ^{135}Cs, ^{137}Cs). Of these, ^{135}Cs and ^{137}Cs are fission products while ^{134}Cs forms in a neutron activation reaction $^{133}Cs(n,\gamma)^{134}Cs$ of stable cesium. The half-life of ^{134}Cs is fairly short (2.1 years) and thus does not pose a long-term radiological problem. In the short term, it is as important as the longer-lived ^{137}Cs since both emit high-energy gamma rays. In the Fukushima Daiichi fuel and environmental releases, the activity concentration of ^{134}Cs and ^{137}Cs were approximately the same. Today, in 2018, the activity of ^{134}Cs is only about one tenth of that of ^{137}Cs. ^{135}Cs and ^{137}Cs are fission products of ^{235}U and ^{239}Pu; the fission yields are high at 6.6% (U) and 7.6% (Pu) for the former and 6.2% (U) and 6.6% (Pu) for the latter. Mass-wise, both thus occur at the same levels in irradiated fuel. Due to their very different half-lives of 2 300 000 years (^{135}Cs) and 30 years (^{137}Cs), the activity of the latter is about 100 000 times greater than that of ^{135}Cs. Accordingly, ^{135}Cs does not form any radiological risk in a nuclear accident but is in

the very long-term one the most important radionuclides with respect to potential release and migration of radionuclides from spent nuclear fuel into the biosphere.

With the exception of the extremely rare francium, cesium is the heaviest alkali metal. Due to its large size and low charge (+1), cesium is the most electropositive element and forms highly soluble ionic compounds. Due to this radioactive cesium isotopes are readily released from nuclear fuel in accidental events, such as the event at the Fukushima Daiichi plant. In spent nuclear fuel, most radiocesium occurs as dissolved in UO_2 matrix and in metallic precipitates. However, a large fraction occurs in the readily soluble fraction (also called instant release fraction), in UO_2 grain boundaries, cracks, and caps. After decay of the very short-lived radionuclides (such as ^{131}I), ^{137}Cs forms together with ^{90}Sr most (99%) of the radioactivity in spent nuclear fuel and in nuclear fallouts. Of these two radionuclides, ^{137}Cs poses a higher radiological risk due to its high gamma energy, high solubility, and tendency to effectively accumulate in humans.

Due to their low charge density, Cs^+ ions do not effectively sorb on conventional organic ion-exchange resins. However, there are some inorganic compounds, both natural and synthetic, that show selectivity towards cesium ions. In the environment, mica and clay minerals are the most effective sorbing minerals for cesium. For industrial nuclear waste purification purposes, the most commonly used sorbents are zeolites, silicotitanates, and transition metal hexacyanoferrates, of which the latter is the most selective. These three categories of sorbents are discussed in detail later in the paper.

SECOND PURIFICATION SYSTEM FROM SEPTEMBER 2011 ONWARDS: SILICOTITANATE WITH ZEOLITE AS A BACK-UP

On August 17, 2011 a new water purification system parallel to Kurion-Areva/Veolia system was commissioned. The new system was called SARRY (Simplified water retrieval and recovery system) and was based on radiocesium separation with a crystalline silicotitanate (CST) (3). This exchanger is produced in sodium form by UOP, USA, under the trademark IONSIV™ R9120 (formerly IE-911) (https://www.uop.com/?document=uop-ionsiv-r9120-selective-media&download=1).
Silicotitanates and their use in nuclear waste treatment are discussed later in detail. The system was

designed and constructed by Shaw, USA, Avantech Inc., USA, and Toshiba, Japan. In SARRY there are four 1.95-m^3 (1040 kg) ion-exchange beds in series. Beds are operated in a "merry-go-round" mode: when a breakthrough is observed in the last column, the first column is removed and a fresh column is placed to the end of the series. The columns are heavily shielded due to build-up of high ^{137}Cs loading into the columns (planned maximum value in one column 200 000 Ci = 7.4×10^{15} Bq). In approximately one month after commissioning of the SARRY system, the AREVA/Veolia system was removed from operation and the SARRY system was operational in parallel with the Kurion zeolite system. From June 2012 onwards the SARRY system was mainly responsible for cesium removal while the Kurion system remained as a backup system. In 2011 to 2017 a total of 1.88 million cubic meters of waste water was treated with these systems (Fig. 4). From the maximum annual volume of 0.35 million cubic meters in 2013 the volume has decreased to almost half of that in 2017. The share of the Kurion system of the total treated volume was 62% in 2011, on average 17% from 2012 to 2016, and only 5% in 2017.

Figure 4. Volumes of waste waters treated by the SARRY and Kurion water treatment systems at the Fukushima Daiichi plant from 2011-2017. Derived from TEPCO press releases.

The ^{137}Cs activity concentration of the feed to the system decreased from greater than 10^9 Bq/L in 2011 by two orders of magnitude to approximately 2×10^7 Bq/L in 2016. Thereafter, the feed activity concentration of SARRY has remained at this level while the feed activity concentration of the Kurion system increased to 9×10^7 Bq/L in 2017, the reason of which is unknown.

Figure 5. ^{137}Cs concentration (Bq/L) in the feed to the SARRY and Kurion water treatment systems at the Fukushima Daiichi plant from 2011-2017. Derived from TEPCO press releases. One GBq/L (10^9 Bq/L) of ^{137}Cs corresponds to chemical concentration of 0.2 µmol/L and one MBq/L (10^6 Bq/L) to 0.2 nmol/L.

The salinity of the waste water has decreased considerably since 2011. Initially, the water was sea water that was injected into the reactor buildings. The first reported chloride concentration in June 2011 was 16 g/L, close to the value in sea water (19 g/L). From mid-2013 onwards the chloride concentration has been below 1 g/L; from 2016 to 2017 the average concentration was 0.26±0.07 g/L. The reverse osmosis process removes most of the salts from the liquids, leaving typically only 1

to 2 ppm (0.001-0.002 g/L) chloride in the solution. Due to the daily intrusion of 500 m^3 (by February 2016) of groundwater and rain water into the reactor buildings, the salinity has increased by two orders of magnitude as the circulated waters return to the water purification system. The total daily volume of waters circulated to the reactors from the water purification system is approximately 200 m^3. Thus we may assume that the salinity of the intruding groundwater and rain water is reduced by a factor of about 1.5. Several countermeasures have reduced the daily amount of groundwater and rain water intrusion to 110 m^3 by February 2018 (TEPCO Fukushima Daiichi prompt report, April 23, 2018).

Figure 6. Chloride concentration (ppm = mg/L) in Fukushima Daiichi plant waste waters. Derived from TEPCO press releases.

During the operation years 2011 to 2017, the decontamination factor for radiocesium (DF) of the two systems has varied in a wide range of about two orders of magnitude. The decontamination factors of the two systems were practically at the same level. On average, the DF of SARRY was 71 000 (range 1900-560 000) and 61 000 (range 2600-320 000) for the Kurion system. In both systems there was no correlation observed between the DF and the salinity (chloride concentration), which is somewhat surprising since one would expect higher DF as the salinity decreased. After removal of the Areva/Veolia system, the DF of the Kurion system increased by two orders of magnitude. During this time the salinity, which affects performance, did not change very much yet. Thus, we may assume that the Areva/Veolia system had an antagonist effect on the performance of the Kurion system. Furthermore, the Kurion system run alone performed as well as the combined Kurion-Areva/Veolia system.

Figure 7. Decontamination factor for ^{137}Cs of the contaminated water purification systems at the Fukushima Daiichi plant. Derived from data provided in TEPCO press releases.

While there was no difference in DF observed between the two water treatment systems, the processing capacities varied considerably (Table 3). The Kurion system created 2.5 times more

secondary solid waste even though it was used for only 20% of the waters. The processing capacity, (i.e., the number of bed volumes of water per unit bed volume of exchanger) treated by SARRY was about ten times higher than that of the Kurion system. Considering the clear decrease in salinity of the waters, one would expect that much higher processing capacities would have been achievable in the later years (such as 2013 onwards). However, the renewal frequency of the beds has not changed significantly over the whole 6.5-year period. In the case of the Kurion system, 320 to 410 m^3 of waste was processed per bed in 2011 but the volume increased on average to only 470 m^3 in 2014 to 2017. In the case of SARRY the increase was somewhat higher, from 1700 to 2700 m^3 in 2012 to on average 7300 m^3 in 2014 to 2017. Furthermore, due to the decreasing ^{137}Cs concentration in the feed, the ^{137}Cs loading in beds greatly decreased over the years. Assuming an average ^{137}Cs concentration of 10^9 Bq/L, the average radiocesium loading in one bed for SARRY before October 10, 2011 was approximately 60 000 Ci (2×10^{15} Bq) while that of the Kurion system was approximately 10 000 Ci (4×10^{14} Bq). In 2016 the corresponding values were much lower, namely 3000 Ci (SARRY) and 300 Ci (Kurion). Even in the early phases, the planned maximum value of 200 000 Ci per bed for SARRY was not exceeded, not mentioning later years. Running the columns much longer thus would not have been limited by excessive build-up of cesium loading in the columns.

Table 3. Processing capacity data for SARRY and Kurion water treatment systems at the Fukushima Daiichi plant. Derived from data provided in TEPCO press releases.

Years 2011-2017	Kurion	SARRY
Number of beds	763	192
Cubic meters of exchanger used	917	374
Tonnes of exchanger used	824	390
Processing capacity[1] (bed volumes)	392	3760
Cubic meters of waste treated with 1 kg of exchanger	0.44	3.62

[1]Processed waste water volume divided by the volume of exchanger beds

Radionuclides of strontium

The most important strontium radionuclide is ^{90}Sr. In Fukushima Daiichi waste effluents the activity concentration of ^{90}Sr was highest after that of ^{137}Cs, being about one tenth of that of ^{137}Cs. ^{90}Sr is a fission product of ^{235}U and ^{239}Pu, with fission yields of 5.7% and 2.0%, respectively. ^{90}Sr is a pure beta emitter with beta particle maximum energy of 0.54 MeV. It is also parent to a short-lived ^{90}Y, which emits high maximum energy beta particles of 2.27 MeV. The two nuclides are typically in radiochemical equilibrium, meaning that their activities are the same. The half-life of ^{90}Sr is approximately the same as that of ^{137}Cs (29 years). Another radiostrontium isotope at approximately the same fission yield as ^{90}Sr is ^{89}Sr, which also is a pure beta emitter with maximum energy beta particles of 1.48 MeV. The half-life of ^{89}Sr is, however, only 50 days and thus it is important only in the early months after the fission process has ended. Radiologically, ^{90}Sr is not as harmful as ^{137}Cs but when ingested enriches primarily into bones.

Strontium is an alkaline earth metal and its chemistry resembles calcium, the next lighter element in the alkaline earth metals series. As an alkaline earth element, strontium has only one oxidation state (+II) and forms Sr^{2+} ions in solutions. Its compounds are typically ionic and very soluble. Only carbonates, phosphates, sulfates, and oxalates are less soluble. In spent nuclear fuel Sr is primarily as dissolved in uranium dioxide matrix, but a small fraction (approximately 1%) is in the so-called instant release fraction in grain boundaries, cracks, and gaps.

Since the charge of the strontium ion is low and its size is rather large, the electrostatic affinity towards ion exchangers is typically not very high. There are, however, some exceptions such as crown ethers, titanates, and silicotitanates, of which the ion-exchange properties of the latter two will be described in detail later.

PURIFICATION OF REVERSE OSMOSIS RETENTATE BY ALPS

To purify the saline reverse osmosis retentate from radionuclides, a new system known as ALPS (Advanced Liquid Processing System) was installed at the Fukushima Daiichi plant in 2013. The purpose of the system was to reduce the radionuclide concentrations to levels that would permit discharge of the treated waters to sea. Initially, altogether 62 radionuclides were to be removed. Today only one third of these radionuclides are left; all others have decayed. There are currently three parallel ALPS systems. The first one, designed by Energy Solutions, USA, was commissioned in

March 2013. This system consists of three phases, namely pretreatment, sorption, and end-polishing (Fig. 8). In pretreatment, ferric hydroxide floc removes primarily hydrolysable radionuclides, such as transuranium elements, ^{60}Co, and ^{54}Mn. The carbonate precipitation removes calcium and magnesium, which strongly interfere with the removal of radionuclides in the sorption phase, particularly in the case of strontium. Carbonate precipitation not only lowers the calcium and magnesium concentrations from hundreds of ppm to less than 5 ppm but also removes ^{90}Sr in excess of 90% (4). The precipitate forming at this stage is a mixture of calcium carbonate and magnesium hydroxide. Magnesium is precipitated as hydroxide since it is much less soluble than magnesium carbonate. The overall removal of radionuclides in the pretreatment phase was reported to exceed 95% in the laboratory tests supporting the design of the system (4). The sorption phase consists of sixteen 1-m^3 sorbent beds containing inorganic ion exchangers, chelating organic resins, activated carbons and hybrid organic/inorganic sorbents. According to the TEPCO Press Conference handout from June 25, 2012, there are seven types of sorbents (Table 4). A major role in these beds are playing by the cesium-selective CsTreat® (hexacyanoferrate) and the strontium-selective SrTreat® (titanate) materials developed and/or manufactured by the authors of this article (5). The properties of these sorbents will be discussed in detail later. A second Energy Solutions ALPS system became operational in September 2014. It is very similar to the first ALPS, with the exception that ferric hydroxide coprecipitation was removed and that there were two additional sorbent beds (TEPCO Press Conference handout from September 11, 2014). Both Energy Solutions ALPS systems have three parallel lines. A third ALPS system, constructed by Hitachi, Japan, was commissioned in October 2014. It is based on cesium and strontium removal with five silicotitanate beds. Furthermore, instead of coprecipitation this system uses four filters in front of silicotitanate beds (6,7). Additional information on these filters is not available. The silicotitanate used in this system seems to be UOP CST treated with dilute NaOH solution.

Figure 8. Flow diagram of the first ALPS (Advanced Liquid Processing System) commissioned in March 2013 at the Fukushima Daiichi plant to purify reverse osmosis retentates.
(http://www.tepco.co.jp/en/decommision/planaction/alps/index-e.html).

A further system to purify reverse osmosis is the Kurion mobile system (Fig. 9), which was operational in December 2014. Its purpose was to reduce the radiostrontium concentration by a factor of 10 to 1000 in the reverse osmosis retentates prior to their treatment in ALPS. This system has stainless steel filters (SS filters) to remove coarse particles, an ultafiltration unit (UF) to remove colloidal matter, and adsorption beds. The sorbent used in these beds is not known.

Figure 9. The Kurion mobile system to reduce radiostrontium concentrations in the Fukushima Daiichi reverse osmosis retentates prior to their treatment in ALPS. From TEPCO Press Conference handout from October 2, 2014.

As approximately half of the water going to reverse osmosis is recycled back to reactors for cooling, we may assume that the salinity of the reverse osmosis retentate is doubled from that in the solution going to the SARRY/Kurion systems. As seen in Fig. 6, the salinity has greatly decreased during the seven years. The chloride concentration in 2011 was 5300 ppm; the value was 1100 ppm in 2012, 620 in 2013, and 370 in later years (all average values). Even the latest chloride concentrations were fairly high compared to typical ground water concentration. In the sea water that was injected into the reactors in the early phases, the chloride and sodium ions formed 73% of the total ionic strength of 0.7 mol/L. This is not the same for groundwaters, which are the source of ions excluding the very early phases. We are not aware of the groundwater composition at the Fukushima Daiichi area. However, based on general knowledge of groundwaters the concentration of sulfate is on the same level as that of chloride. Furthermore, potassium, calcium, and magnesium concentrations may also be at the same level as that of sodium. The variation of their concentrations and mutual ratios vary, however, very much from case to another (8). Sylvester at al. (4) reported that the reverse osmosis retentates have a pH close to neutral and have high total dissolved solids contents up to 20 g/L. This very high value refers to the very early phases of the separation when there was still sea water in the system.

By the end of 2017, the ALPS systems had treated altogether 842 000 m^3 of water coming from the reverse osmosis (RO) system. ALPS 1 performed 52% of the treatment, ALPS 2 performed 35%, and only 13% was performed by ALPS 3. The last system, ALPS 3 (initially referred to as "high performance ALPS") was in operation only for 1.5 years, suggesting that it did not work. Since March 2016 it has been completely out of operation. In the test run of the ALPS 3 system in 2015, ^{90}Sr was removed from 82 000 m^3 of reverse osmosis retentates with a decontamination factor between 100 and 1000; these values were far below than those obtained with ALPS systems using sodium titanate (see next section). A probable reason for the failure is that evaluation tests were performed with a sea water simulant containing salts corresponding to their actual concentration in sea water (6). This procedure probably underestimates the effects of calcium, magnesium, and potassium which are, unlike in sea water, important ions in groundwater that are the source of ions after the very early phase. In fact, these ions compete much more strongly with cesium/strontium than sodium ions (9).

The performance of the ALPS systems in radionuclide removal has not been well reported. Table 5 provides information on the performance of ALPS 1 in March 2013, the only operational system at the time. The results are likely from preliminary tests, since ALPS 1 started operation in March 2013. At that time, already 37 out 62 target nuclides were under their limits of detection. After purification, all other radionuclides were below the required values to allow discharge into the sea. As stated earlier, the coprecipitation pretreatment removed 95% of radioactivity. This does not apply to the radionuclides that do not precipitate as hydroxides or carbonates (Cs, I, Tc, and probably Ru and Sb). We may thus assume that the decontamination factor reported in Table 5 for these nuclides represent those for the sorption phase. For the radionuclides that form hydroxides and carbonates (Co, Ni, Sr, Pu, Am, Cm), the decontamination factor of the sorption phase is lower than that reported in Table 5 by a factor of 20 if we assume that 95% of all these elements were removed in the pretreatment phase. The decontamination factor of SrTreat for ^{90}Sr sorption is 60 000 000, which is an enormously high value. For CsTreat, the decontamination factor would be the same as reported in Table 4 (56 000). In the full-scale test run it was observed that the ALPS 1 system did not remove ^{60}Co, ^{106}Ru, ^{125}Sb, and ^{129}I sufficiently to reach the required activity level. This problem was solved by adding two more sorbent beds to ALPS 2 and changing sorbents (TEPCO Press Conference handout from July 31, 2014). It was not revealed which sorbent(s) was changed. The waters already

treated with ALPS 1 with insufficient removal of ^{60}Co, ^{106}Ru, ^{125}Sb, and ^{129}I were retreated with ALPS 2.

Table 5. Radionuclide concentrations (Bq/L) in reverse osmosis retentate, decontamination factors obtained with ALPS 1, and the factors by which the concentrations are below the required level. The values in the two last columns are minimum values, since all the radionuclide concentrations were below detection limits. Minimum values were calculated using the detection limits. Data extracted from TEPCO Press Conference handout from March 29, 2013.

While the performance of the Kurion mobile strontium removal system has not been reported, the target was to achieve a 10 to 1000-fold reduction in the ^{90}Sr concentration. The Kurion system produces additional secondary solid waste but due to lack of information it is unclear what benefit f it provides in final purification of the waste effluents.

The secondary solid waste from the ALPS systems, sorbents, and precipitation sludges are stored in High Integrity Containers (HIC). The sorbents from the Kurion Sr-removal system are probably also stored in HICs, which are made of polyethylene and have a volume of 3.8 m^3 (diameter 1.6 m, height 1.9 m). In June 2012 (TEPCO Press Conference handout from June 26, 2012) it was estimated that 500 containers are generated annually (50 from sorbents and 450 from sludge). The HICs are stored in concrete containers of approximately 20 m^3 (TEPCO Press Conference handout from March 29, 2013); two HICs are stored in each container. At the end of 2017 there were altogether 2621 of these containers. The total volume of the containers is approximately 50 000 m^3 and the total volume of the HICs approximately 20 000 m^3. It is not known what fraction of these volumes are generated by the Kurion mobile strontium removal system's spent sorbents. These figures, however, show that the volume reduction factor (volume reduction factor = volume of produced solid waste divided by the volume of treated waste effluent) of the ALPS and Kurion strontium removal systems in total is approximately 20 (based on the volume of the containers) and 50 (based on the volume of HICs). These values are evidently not very high, which means that very large amounts of secondary solid waste have been generated and are still being generated.

In 2015, TEPCO reported that all other reverse osmosis retentates will be treated by May 2015 but not the highly saline 20 000 m^3 generated in the early phases of the accident due to injection of sea

water into the reactors. In February 2016 this volume decreased to 11.000 m^3 and has remained the same since.

The nearly million cubic meters of waters purified with the ALPS systems are stored onsite in 650 tanks each with 1000 m^3 of volume. The waters are still stored in the tanks since they contain tritium, which the ALPS systems cannot remove. Tritium (^3H) is bound to water as ^3HHO and is therefore not separable by any reasonable method. Efforts to remove tritium by electrolytic enrichment processes have not lead to practical applications due to extremely high costs. The tritium levels in the effluents are fairly high (1×10^6 to 5×10^6 Bq/L). Regulations require levels below 6×10^4 Bq/L; the solution should thus be diluted by a factor of 50 to 100 prior to release into sea. The reason for not doing this is probably not technical or based on radiation safety but is of a political nature.

PREPARATION, STRUCTURE, AND ION-EXCHANGE PROPERTIES OF THE ION EXCHANGERS USED AT THE FUKUSHIMA DAIICHI NUCLEAR PLANT FOR CESIUM AND STRONTIUM REMOVAL

The preparation, structure, and ion-exchange properties of the four types of inorganic ion exchangers used at the Fukushima Daiichi nuclear plant to remove radiocesium and radiostrontium from waste effluents are reviewed in the following sections. These exchangers are zeolites, transition metal hexacyanoferrates, titanates, and silicotitanates. In addition to general information, examples of their use in nuclear waste treatment processes outside of Fukushima are given.

Zeolites

There are a number of naturally occurring and synthetic zeolite minerals. They all are microporous crystalline aluminosilicates with a general formula of $M_{y/z}[(SiO_2)_x(AlO_2)_y] \times nH_2O$, where M is an alkali metal or alkaline earth metal with a charge of +z. The framework consists of SiO_4 and AlO_4 tetrahedra, which share all four oxygens. More than a hundred different zeolite structures are known. Due to the replacement of tetravalent Si^{4+} with trivalent Al^{3+}, the framework carries an electric charge that is balanced by alkaline or alkaline earth metal ions. The aluminosiliacate

structure in zeolites forms a rigid three-dimensional framework containing channels and cavities where the alkaline and alkaline earth metal ions and water molecules are located (Fig. 10). These metal ions are mobile and exchangeable to ions in solutions in contact with zeolites. (10).

The two factors affecting the selectivity towards ions in zeolites are the dimensions of the cavities

exchange properties of KURION herschelite in simulating contaminated water. *Journal of Nuclear Science and Technology*, 51:886-893.
